

C++ Parallel application for Traveling Salesman Problem resolution using genetic algorithm

Parallel and Distributed System: Paradigms and Models
2019 / 2020

Berti Stefano

Abstract

The aim of this project is to implement a genetic algorithm for the resolution of the Traveling Salesman Problem and to parallelize it with two different mechanism:

- C++ standard threads and mutex
- Fastflow library

1 Problem description

Genetic algorithms mimic natural evolution. In order to do that, we need a population of chromosomes, a way to assign an affinity score to each chromosome and transform it into a probability to select which elements of the population will survive (and so will reproduce), how those chromosomes reproduce and how a mutation can occur. We also have 2 fixed probabilities for crossover and mutation to happen.

- **City:** the city is made by two vectors of integers for the 2 coordinates (node i has coordinates $(x[i], y[i])$, each x has range $[0, 640]$, each y has range $[0, 480]$). It also has an adjacent matrix (vector of vector of bool) of dimensions $\#nodes * \#nodes$ for the connections of nodes in the city (roads), which is automatically optimized to use just 1 bit for each element.
- **Population:** it is a matrix (vector of vector of int), where each row contains a sequence of $\#nodes$ integers, and each integer represents a node
- **Affinity:** for each element x , $affinity[x]$ is the probability that x will be selected for reproduction, and it is calculated as the inverse of the path length, normalized with respect to the sum of all paths length in order to obtain a proper probability
- **Reproduction:** a crossover occurs with a certain probability, otherwise one of the 2 picked paths is returned. 2 paths A and B can create a new path C by generating 2 random numbers i and j and putting the

Figure 1: Initial problem with 20 nodes

subsequence $B[i, j]$ in A . Then we check if C is a feasible path using the adjacent matrix, and if not we try again until we generate a feasible C .

- **Mutation:** a mutation occurs with a certain probability to every new generated path, and it is a random shuffling of two positions in the generated C path. The probability that a mutation does not occur is 0.9, which is a good trade-off (too high probability leads to casuality, too low probability leads to no/slow evolution). Then we check if C is a feasible path using the adjacent matrix, and if not we try again until we generate a feasible C .

It is possible to plot the city, the connections among the nodes (blue dotted line) and the best solution found until the current iteration at runtime by compiling with **make compile-graph**, this is available only for the sequential version and it has huge impact on the performance, but it shows the correctness of the algorithm. This algorithm is not guaranteed to find the best solution of TSP, which is a NP-HARD problem, but can find a good starting point for successive improvements.

2 A first approach

The first approach that I thought was to use the fact that we can divide each iteration in two phases, and each phase is parallelizable with a map. It was a

Figure 2: Solution found after some iterations

pipeline with feedback composed by a map-reduce to calculate the affinity of each path by inverting the length with a reduce phase to compute the sum and to normalize each affinity in order to obtain proper probabilities and another map for the reproduction stage. Each worker had its own chunk of the population/affinities to compute, and the fastflow version was implemented with a `parallelforreduce` to compute the length of each path and to reduce on the sum, and another `parallelfor` to compute the new population. This approach ideally reduces the completion time by a factor of nw , but it needs to have a barrier between the two phases and this leads to a lower speedup, because I need to have proper probabilities for the second stage to be executed. The good of this approach is that we have just one population with always the same size, independently by the number of workers and so taking in account crossovers with every possible pairs of the entire population. But the synchronization and the reduction are a bottleneck for this kind of skeleton. Due the fact that it is a pipeline of farm, I could apply a `map fusion`, using the sum as an accumulator state, and move from `a stateful skeleton to a stateless one` with a modification to the initial problem. When the population is big, the probabilities are all small and not very different because the path lengths don't differ too much, so the probabilities become less meaningful as the population increases (but anyway useful to keep the correctness of the algorithm). If I assume to have more than one independent populations where each one tries to solve the problem, I will not make the same computation as before because I won't be considering anymore the possibility of crossover among each pair of chromosomes of the entire

Figure 3: The first approach

population, but I will get rid of the synchronization among workers, increasing performances and decreasing the completion time.

3 The second approach

This approach is a simple farm over the task **evolve**, which is a composition of the two stages **calculate affinities** and **reproduce**. This composition is also known as **normal form**, and ensures the best performances with the lowest number of resources. In this way, we don't need to reduce on the sum. Considering that, provided enough iterations i , the scheduler and the gatherer times are negligible (the emitter just have to pass the parameters to the workers, and the gatherer just have to find the best solution over the nw solutions returned by the nw workers), the completion time is

$$i * T_w / nw$$

So, by increasing the number of workers, I expect to see a linear speedup. My machine has 5 cores, so I also expect to have the **knee** at 5 workers. The heaviest data structure is the **population** one, which has dimension 0.08MB (4 byte(int) * 20 * 1000), while affinities has size 0.008MB (8byte(double) * 1000) and city as a very small size around 320byte (8byte(double) * 2 * 20 and 20*20 bit for the adjacent matrix). My cpu has 3 caches L1, L2 and L3 of size respectively 9MB, 1.5MB and 350KB, so data easily fits the L3 cache and I don't expect a superlinear speedup for cache fitting reasons. Anyway, I implemented the pick.candidate function to cost $O(n)$ in the worst case, where n is the population size, because it generates a random float and decreases it with the probabilities one after the other until it becomes negative, and then the algorithm selects the candidate as the number of iterations needed. This could generate a superlinear speedup, because increasing the number of workers,

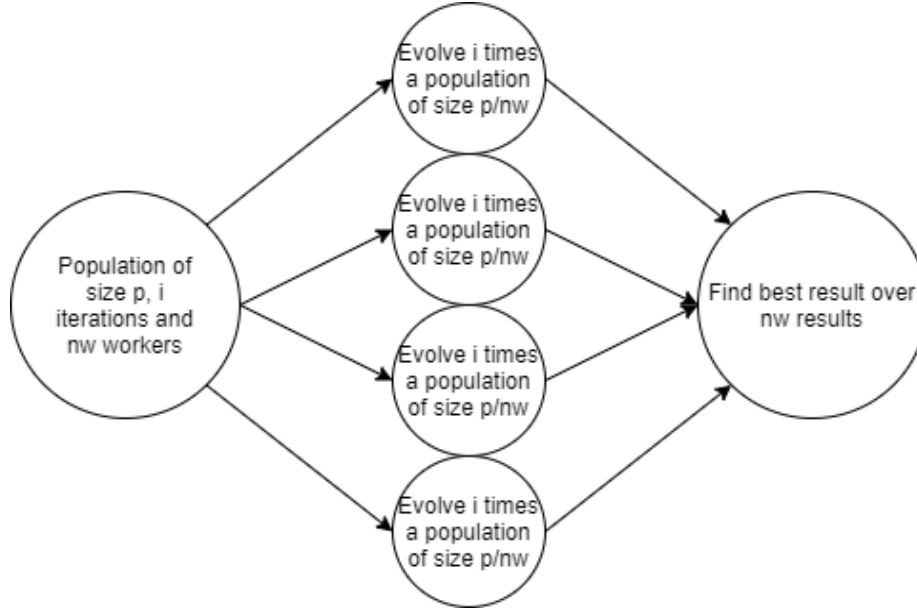

Figure 4: Second and final approach

we are not reducing only the number of chromosomes that each worker has to generate, but also the time needed to generate each of them.

Table 1: Measured completion time, real completion time, gap between the two and gap percentage w.r.t. measured time for local execution with 20 nodes, 1000 chromosomes and 1000 iterations (time in microseconds). My machine has 5 cores.

nw	$T(nw)$	$(T(1)/nw)$	gap	$T(nw)/gap$
1	8884752	8884752	0	0%
2	4187312	4442376	-255064	-6%
3	2730646	2961584	-230938	-0.8%
4	2004171	2221188	-217017	-10%
5	1609943	1776950	-167007	-10%
6	1644261	1480792	163469	9.94%
7	1718324	1269250	449074	26.13%

?

4 Performance discussion

As we can see from the plots, in both the local and remote machines we have the knees in the expected points: at 5 in the local speedup because my machine

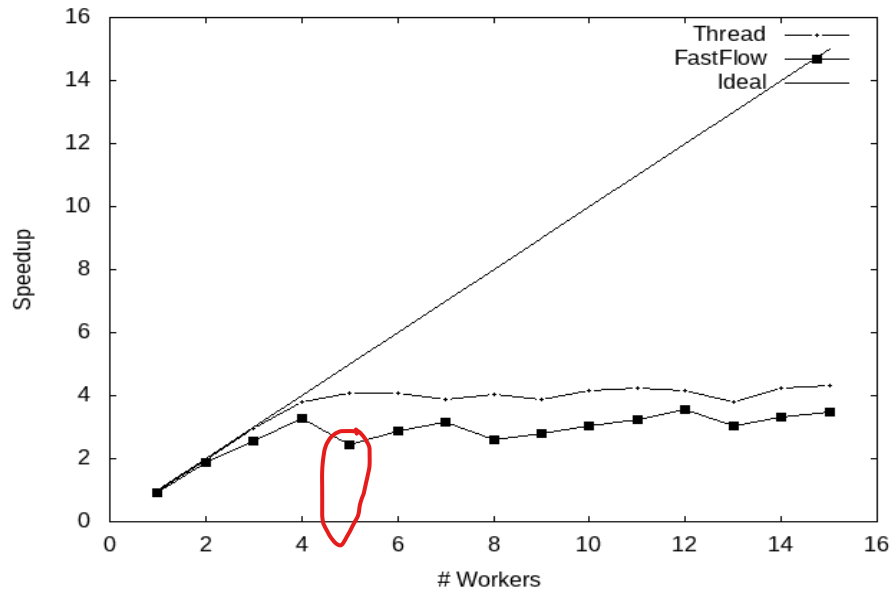

Figure 5: Local speed obtained with 20 nodes, 1000 chromosomes, 1000 iterations and 5 cores

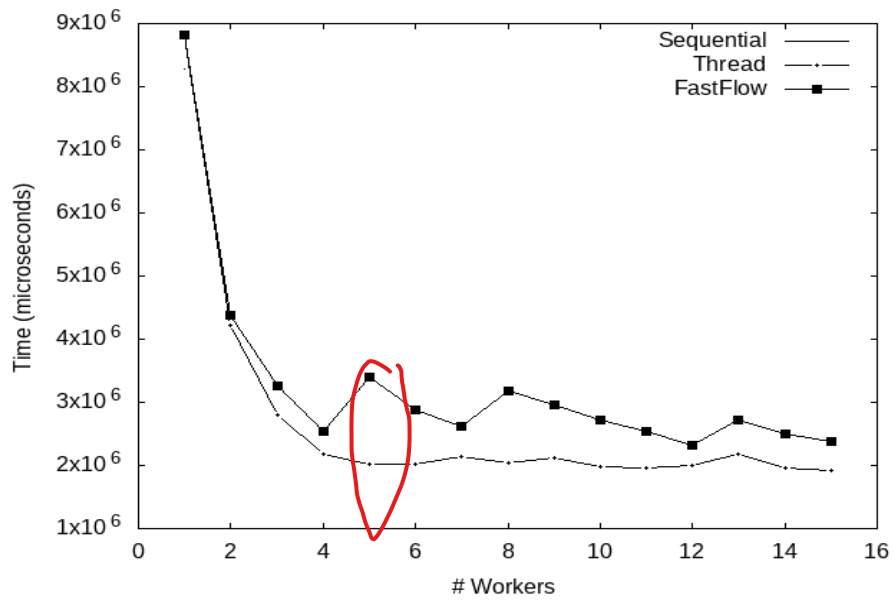

Figure 6: Local time obtained with 20 nodes, 1000 chromosomes and 1000 iterations and 5 cores

Figure 7: Remote speedup obtained in phi19 machine, with 20 nodes, 1000 chromosomes, 1000 iterations and 256 cores

has 5 cores and at 256 in the remote machine because it has 256 cores. The gap between the real speedup and the ideal one can be motivated by overheads, so the time needed to generate each thread (which becomes not negligible when `nw` gets higher) and the time to join them and to get the best results over the `nw` ones. The thread version is faster w.r.t. the FastFlow one because uses standard mechanisms of `c++`, which have less overheads w.r.t. the FastFlow library, even if the computation model is exactly the same.

5 Difficulties

At a certain point, I had a bottleneck in the remote machine that doesn't allow me to have a speedup higher than 3. I investigated this problem for days to find out that my bottleneck was caused by the `rand()` function, that I used for the crossover and mutation functions, and so it was called a lot of times every cycle. This, together with the pick candidate, made my development and my analysis a lot more difficult. To overcome this issue, I created the `MyRandom` class, which sets up just once for every worker the 3 different uniform distribution that I used in the program, which are `[0, n_nodes)(int)`, `[0, pop_size)(int)` and `[0, 1](double)`. I didn't create the graphical visualization at runtime for the parallel versions because to do it I should have changed my stateless skeleton to a stateful one with a resource shared state composed by the shortest path length

found and the relative shortest path, with an huge impact on the performances, that would have limited my speedup to the ratio $T_w/T_{stateaccess}$.

6 Other improvements

I always compile my code with the -O3 flag in order to make other optimizations, like vectorization, which occurs in various part of the code: when we push work in the farm of FastFlow, in the main loop of the Evolution node of FastFlow (basic block), in the affinities normalization, in the main loop of the thread (basic block), in the normalization of the sequential part, in the loop that starts the thread and in the loop that generates the population. Vectorization cannot happens in the main loop, because we need an **if** statement to check if the path just generated is the best found until now. I tried to parallelize other part of the code, for example the random initialization of the city and of the population, but I didn't get any improvements, so I removed it. The code can be optimized more, in the algorithmic way by rewriting the pick_candidate function with a manipulation of the probabilities and using the binary search, or selecting the candidates with another approach, for example using an heap or by sorting them.

7 Conclusions

I experimented first to preserve the flow of the algorithm with the usage of synchronization between stages and shared vector (that could also raise false sharing issues), then I decided to generate more smaller flows of execution of the algorithm in order to get the best result at the end of the computations. If we want to see which is the best path found from the workers at runtime, we have to be careful at the state access pattern, where the state is made by the best length and the best path. In the thread version, we can overcome this issue with the usage of a mutex around the block which controls (and possibly sets) the best state w.r.t. the new one, but then the maximum speedup reached would have been the ratio between T_w/T_a , where T_a is the time needed to access the state.
